Received February 24, 1997

Abstract: Density functional calculations have been performed on the excited states of Cr(CO)₆. In contrast to the generally accepted assignment of the spectrum by Gray and Beach¹ ² but in agreement with recent CASSCF/CASPT2 calculations by Pierloot et al.¹ we find the low-intensity absorption at the low-energy side of the first charge-transfer (CT) band not to be due to ligand-field (LF) excited states, but to symmetry forbidden CT excitations. In Cr(CO)₆ as in other d⁶ metal–carbonyl complexes,⁴ –⁶ the LF states are at high energy. The calculations show that two states arising from the low-energy CT configuration have dissociative potential energy surfaces, in agreement with the experimentally observed photodissociation of the Cr–CO bond upon low-energy absorption. The photodissociation is therefore occurring from CT and not from LF states. This leads to a reassessment of the role of LF states in metal–ligand photodissociation: it is not necessary to excite to LF states in order to induce photodissociation of ligands, and such dissociation, when observed, does not prove that the excitation was to a LF state.

1. Introduction

The accepted picture of photochemical dissociation of metal–ligand bonds gives a predominant role to ligand-field excitations.³ ⁸ The argument may be illustrated with the well-known qualitative molecular orbital energy diagram for an octahedral d⁶ transition-metal complex depicted in Figure 1. In this paper we will take Cr(CO)₆ as the prototype system. The ligand–metal antibonding e_g orbitals, which are π-bonding between the metal and the CO ligands, and a lone pair on the ligand, as illustrated for the d⁶ component in the figure. Excitation to the e_g orbital reduces the number of electrons in the π-bonding t2g orbitals and, more importantly, occupies the strongly antibonding Cr-d,π-π*CO-5σ e_g orbital. It is therefore understandable that the corresponding excited state potential energy curve (PEC) along the metal–CO dissociation coordinate is dissociative, the heterolytic dissociation leading to CO in the ground state and Cr(CO)₅ in the t2g → dπ* excited state. The departure of the antibonding CO will lead to strong lowering of the orbital energy of the dπ⁎, the excitation energy therefore being much lower in Cr(CO)₅ than in Cr(CO)₆. This is also necessary since the energy available for the breaking of the Cr–CO bond is just the difference in excitation energy in the initial complex and in the photoprodut.

The excitation spectrum of Cr(CO)₆ contains a low-energy low-intensity shoulder that was assigned a long time ago by Gray and Beach² to the ligand field excited state ¹T₂g belonging to the t₃g⁵e_g¹ configuration. At higher energies the high-intensity charge-transfer bands occur, with a weak band in between that has been assigned to the ¹T₂g(t₂g⁵e_g¹) LF state. This assignment appeared to be confirmed by the original extended-Hückel² and more recent semiempirical INDO/S C¹ and ab initio RHF calculations. There was also little reason for revision of this assignment, since irradiation in the low-energy shoulder, presumably populating the lowest LF state, leads to photodissociation of CO, in perfect agreement with the expectations. The Cr–CO photodissociation has been the subject of a number of time-resolved spectroscopic investigations,¹¹ –¹⁰ which have established that the dissociation is fast (within 350 fs)¹⁸ and have mainly been directed toward the understanding of the effect of the solvent on the photodissociation dynamics and the reaction processes (vibrational relaxation and solvation). The LF nature of the photoactive excited state has not been questioned.

However, we have recently found in several d⁶ TM complexes that the relation between the lowest excited state at equilibrium geometry and the photochemistry is less direct than assumed in the “standard model”. In particular, the LF excitation to a metal–CO antibonding e_g-type orbital was found

to lie at relatively high energy. On the other hand, the \( \sigma \)-antibonding character of such orbitals proved to be not only extremely strong but also short ranged. As a consequence, as soon as the metal–CO bond becomes longer, the pushing-up effect of the antibonding character rapidly diminishes, and the orbital energy and excitation energy come down precipitously. The initially high-lying LF state is therefore characterized by a \( \sigma \)-antibonding orbital between the metal and a ligand (L) other than CO (to \( L = \text{Mn(CO)}_3 \) in \( \text{Mn}_2(\text{CO})_{10} \); to Cl in \( \text{MnCl(CO)}_5 \); or to a \( \pi^* \) orbital of an \( \alpha \)-diimine ligand in \( \text{fac-MnCl(CO)}_3(\alpha \)-diimine)\). In this last example the low-energy excitation is truly of the metal–ligand charge-transfer (MLCT) type.

It is improbable that the situation in the prototype \( \text{Cr(CO)}_6 \) system would be different. For this reason and because the system affords clear analysis of the electronic structure because of its high symmetry, we have been investigating the photochemistry of this system. As before we use density functional (DF) calculations to obtain the PECs of the ground state as well as excited states. The DF calculations afford a straightforward interpretation of the electronic structure in terms of a molecular orbital picture. The DF calculations find, as in the other \( d^6 \) complexes, the LF excitations to be at high energy at \( R_e \), and not to be responsible for the photolabile low-energy weak-intensity transition. We have been encouraged by the very recent calculations by Pierloot et al., who have performed CASPT2 calculations for the excited states of \( \text{Cr(CO)}_6 \). These calculations, which may be considered the most sophisticated ones to date, find, in agreement with our DF calculations and contrary to the previous calculations, the LF excited states to be at much higher energy than has been assumed before.

In the present paper we present a re-interpretation of the photochemistry of \( \text{Cr(CO)}_6 \) upon low-energy excitation (at ca. 4.0 eV), based upon calculated potential energy curves (PECs) along the \( \text{Cr}–\text{CO} \) dissociation coordinate. Our interpretation for \( \text{Cr(CO)}_6 \) is in line with the findings for the other \( d^6 \) systems and leads to a reassessment of the role of LF excited states in the photochemistry. The calculated DF excitation energies at \( R_e \), using the \( \text{ASCF-type of approach originally suggested by Ziegler et al.} \) (see below), will be compared to the recent CASPT2 results.

2. Method

All calculations have been performed with the Amsterdam Density Functional (ADF) program system. This computational scheme is characterized by a density fitting procedure to obtain accurate Coulomb and exchange-correlation potentials and by evaluation of the KS Hamiltonian matrix elements by an accurate and efficient 3D numerical integration method. An uncontracted double-\( \zeta \) STO basis set has been used with one polarization function for the C and O atoms. For Cr a triple-\( \zeta \) 3d,4s basis with one 4p function was used. The 1s O and C cores were kept frozen as well as the 1s–2p cores for Cr atom.

The density functionals included Becke’s gradient correction to the local exchange expression and Perdew’s gradient correction to the LDA expression (VWN parametrization) for the correlation energy. The original proof of the Hohenberg–Kohn theorem is only valid for the ground state of a system. It has been extended to the lowest state of any given symmetry, which is in fact sufficient for the purpose of this paper. However, the \( \text{ASCF-type method proposed by Ziegler et al.} \) for the calculation of excited states has been used to obtain a number of higher excited states as well. This method has been used with good results for atomic and molecular systems, as well as the potential energy surface for the photodissociation of \( \text{H}_2 \) in its first excited state. The results of the \( \text{ASCF-type method are comparable to those of the theoretically better founded time-dependent DFT} \).
method\textsuperscript{37,38} with the adiabatic local-density approximation, which has recently been applied successfully to a number of simple atoms\textsuperscript{39} and molecules.\textsuperscript{40} The method for excitation energy calculation of ref 22 differs from a DSCF method as used in \emph{ab initio} Hartree–Fock methods, where total energy differences are taken from possibly multideterminantal configuration state functions. A crucial element of the scheme of ref 22 is the restriction of total energy calculations to single-determinantal states only. This is a consequence of the requirements for the hole-density that have to be met for the approximate functionals to be applicable. It is, however, not always possible, particularly in a high point group symmetry, to resolve all multiplets of a given configuration from the energies of single determinants only, completely analogous to the situation in the traditional diagonal-sum method for multiplets.\textsuperscript{41,42} In those cases one may sometimes solve the problem by judicious symmetry lowering (e.g. to $C_{2v}$ symmetry in our case, see below). More systematically, if one is prepared to go beyond diagonal-sum approaches and to calculate explicitly specific two-electron integrals,\textsuperscript{43} any multiplet problem may be solved, where the maximum number of non-redundant two-electron integrals may be deduced by group-theoretical methods as developed by Daul.\textsuperscript{44}

We wish to stress that Kohn–Sham molecular orbitals are not just mathematical constructs whose only purpose is to build the electron density, they are physically meaningful (see ref 45 and references therein), in the same way as the MOs of other one-particle models such as Hartree–Fock and extended Hückel. This is related to the fact that the effective local potential of the Kohn–Sham model has as leading terms—apart from the nuclear potential and Coulomb potential of the total electronic density—the potential due to both the Fermi (exchange) hole and the Coulomb hole.\textsuperscript{46–48} The latter builds in effects of electronic correlation and in fact gives the Kohn–Sham MOs an advantage over Hartree–Fock orbitals in cases of strong near-degeneracy correlation. Virtual orbitals, being solutions in exactly the same potential as the occupied orbitals, have the advantage that they lack the artificial upshift and diffuse character of Hartree–Fock orbitals. They are useful for a qualitative interpretation of the electronic nature of excited states.

\section*{3. Results}

In Table 1 the orbital energies of the 3d orbitals, the highest occupied orbital $t_{2g}$ and the empty $e_{g}$ orbital, are given, as well as those of the whole set of empty CO $2\pi^{*}$ orbitals and the Cr 4s orbital. We note that the $e_{g}$ orbital is not the LUMO, as is assumed in the traditional MO scheme of Figure 1, but is actually quite high up in the virtual orbital spectrum. The spread in the CO $2\pi^{*}$ orbitals is substantial, amounting to more than 1.5 eV. It is caused by bonding and antibonding interactions between the CO molecules of the (CO)\textsubscript{6} cage. As a matter of fact, the spread is larger in the empty (CO)\textsubscript{6} cage since the

to $a'$T$_{1u}$ and $b'$T$_{1u}$ are the only ones allowed by both spin and spatial symmetry, cf. the discussions by Beach and Gray$^2$ and Pierloot et al.$^3$ The crucial point for our discussion is that the lowest excitations are calculated to be the $a'$T$_{2u}$, $a'$E$_u$, $a'$A$_{2u}$, and $b'$E$_u$, $b'$A$_{1u}$, $b'$T$_{2u}$ sets of symmetry forbidden charge transfer excitations, both in the DFT and the CASSCF/CASPT2 calculations. These CT excitations are below the LF excitations. With respect to the LF states originating from the (2t$_{2g}$)$_5$(3t$_{2g}$)$_1$ configuration, we observe that the DFT results are again, as for the CT excitations, in between the CASSCF and the CASPT2 results. We have given in Table 2 all excited states that we find up to 5.2 eV, at which energy we encounter the lowest LF state. At higher energies the states arising from the other CT configurations (2t$_{2g}$)$_5$(3t$_{2u}$)$_1$ and (2t$_{2g}$)$_5$(2t$_{1u}$)$_1$ are found, some of which are located below the $a'$T$_{1u}$ and $b'$T$_{1u}$ states of the (2t$_{2g}$)$_5$(9t$_{1u}$)$_1$ and (2t$_{2g}$)$_5$(2t$_{3u}$)$_1$ configurations, but since we obtain basically the same pattern we refer to ref 3 for a discussion of the complete excitation spectrum to the CO 2π* orbitals.

We conclude that our present DFT results for Cr(CO)$_6$ are in line with those for other d$^6$ complexes$^{4,21,6}$ and with the completely independent CASSCF/CASPT2 results. They strongly indicate that the LF excited states are too high to be directly populated when irradiation at ca. 4.0 eV takes place. The low intensity of the absorption at this energy is to be attributed to their symmetry-forbidden nature, not to their LF character. This poses the question how one can explain the observed photochemical metal-CO dissociation at this energy, and in particular what the role of the CT states that are being populated could be in the photochemical process.

We have calculated the PECs along the Cr-CO dissociation coordinate for the states arising from the 2t$_{2g}$ → 9t$_{1u}$ CT excitation. Since the optimized geometry of the Cr(CO)$_5$ product does not differ much from the geometry of the Cr(CO)$_5$ fragment in Cr(CO)$_6$ (cf. discussions in refs 49 and 50), we have kept the geometry of the Cr(CO)$_5$ fragment fixed. The curves as shown in Figure 2 demonstrate that there are, in spite of the CT character of these states, two dissociative or nearly dissociative PECs, of 1B$_2$ and 1E symmetry in the relevant C$_{4v}$ point group, arising from the $a'$T$_{1u}$ and $a'$E$_u$ states. The corresponding triplet states (Figure 2b) are both purely dissociative. This demonstrates that it is not necessary to excite to LF states in order to induce photodissociation of ligands, but that the dissociation may also occur from CT states. The observed photoactivity may therefore not be used for assigning the low-energy absorption to LF excitation. It should also be noted that the singlet PECs are dissociative, so that it is not necessary to invoke intersystem crossing to the dissociative triplet PECs in order to explain the photodissociation. In agreement with this, Joly and Nelson$^{20}$ concluded from their transient absorption measurements that the photodissociation proceeds directly from the initially excited state with no intersystem crossing necessary.

It is possible to understand from the electronic structure why this excitation is photoactive, and one can indeed predict immediately that precisely these B$_2$ and E PECs will be the dissociative ones. The essential element in the explanation is that, even though the excitation is to a CT state at $R_e$, the dissociation is still driven by the presence of a strongly dissociative LF state, which is at high energy at $R_e$ but rapidly lowers its energy upon CO bond lengthening. The symmetry of the dissociative LF state, which can be predicted without calculation, then dictates B$_2$ and E symmetry for the dissociative PECs in Figure 2, as will become apparent.

---

To $a'$T$_{1u}$ and $b'$T$_{1u}$ are the only ones allowed by both spin and spatial symmetry, cf. the discussions by Beach and Gray$^2$ and Pierloot et al.$^3$ The crucial point for our discussion is that the lowest excitations are calculated to be the $a'$T$_{2u}$, $a'$E$_u$, $a'$A$_{2u}$, and $b'$E$_u$, $b'$A$_{1u}$, $b'$T$_{2u}$ sets of symmetry forbidden charge transfer excitations, both in the DFT and the CASSCF/CASPT2 calculations. These CT excitations are below the LF excitations. With respect to the LF states originating from the (2t$_{2g}$)$_5$(3t$_{2g}$)$_1$ configuration, we observe that the DFT results are again, as for the CT excitations, in between the CASSCF and the CASPT2 results. We have given in Table 2 all excited states that we find up to 5.2 eV, at which energy we encounter the lowest LF state. At higher energies the states arising from the other CT configurations (2t$_{2g}$)$_5$(3t$_{2u}$)$_1$ and (2t$_{2g}$)$_5$(2t$_{1u}$)$_1$ are found, some of which are located below the $a'$T$_{1u}$ and $b'$T$_{1u}$ states of the (2t$_{2g}$)$_5$(9t$_{1u}$)$_1$ and (2t$_{2g}$)$_5$(2t$_{3u}$)$_1$ configurations, but since we obtain basically the same pattern we refer to ref 3 for a discussion of the complete excitation spectrum to the CO 2π* orbitals.

We conclude that our present DFT results for Cr(CO)$_6$ are in line with those for other d$^6$ complexes$^{4,21,6}$ and with the completely independent CASSCF/CASPT2 results. They strongly indicate that the LF excited states are too high to be directly populated when irradiation at ca. 4.0 eV takes place. The low intensity of the absorption at this energy is to be attributed to their symmetry-forbidden nature, not to their LF character. This poses the question how one can explain the observed photochemical metal-CO dissociation at this energy, and in particular what the role of the CT states that are being populated could be in the photochemical process.

We have calculated the PECs along the Cr-CO dissociation coordinate for the states arising from the 2t$_{2g}$ → 9t$_{1u}$ CT excitation. Since the optimized geometry of the Cr(CO)$_5$ product does not differ much from the geometry of the Cr(CO)$_5$ fragment in Cr(CO)$_6$ (cf. discussions in refs 49 and 50), we have kept the geometry of the Cr(CO)$_5$ fragment fixed. The curves as shown in Figure 2 demonstrate that there are, in spite of the CT character of these states, two dissociative or nearly dissociative PECs, of 1B$_2$ and 1E symmetry in the relevant C$_{4v}$ point group, arising from the $a'$T$_{1u}$ and $a'$E$_u$ states. The corresponding triplet states (Figure 2b) are both purely dissociative. This demonstrates that it is not necessary to excite to LF states in order to induce photodissociation of ligands, but that the dissociation may also occur from CT states. The observed photoactivity may therefore not be used for assigning the low-energy absorption to LF excitation. It should also be noted that the singlet PECs are dissociative, so that it is not necessary to invoke intersystem crossing to the dissociative triplet PECs in order to explain the photodissociation. In agreement with this, Joly and Nelson$^{20}$ concluded from their transient absorption measurements that the photodissociation proceeds directly from the initially excited state with no intersystem crossing necessary.

It is possible to understand from the electronic structure why this excitation is photoactive, and one can indeed predict immediately that precisely these B$_2$ and E PECs will be the dissociative ones. The essential element in the explanation is that, even though the excitation is to a CT state at $R_e$, the dissociation is still driven by the presence of a strongly dissociative LF state, which is at high energy at $R_e$ but rapidly lowers its energy upon CO bond lengthening. The symmetry of the dissociative LF state, which can be predicted without calculation, then dictates B$_2$ and E symmetry for the dissociative PECs in Figure 2, as will become apparent.

---

Figure 2. (a) Potential energy curves (PECs) along the Cr-CO dissociation coordinate for the singlet states (in C$_{4v}$ symmetry) arising from the lowest excited (charge-transfer) configuration, (2t$_{2g}$)$^5$(9t$_{1u}$)$_1$. (b) The same for the corresponding triplet states.

The mechanism for the photodissociation is in fact mutatis mutandis, the same as that found in the other d$^6$ complexes$^{4,21,6}$ Upon Cr-CO bond lengthening, the antibonding present in the Cr-d$_z^2$-CO-5a e$_g$* orbital (we will denote it as “d$_z^2$”, see Figure 1b) rapidly diminishes. When there is a ligand trans to the leaving CO with a weaker ligand field strength, such as Cl or Mn(CO)$_5$, the “d$_z^2$” orbital precipitously lowers its energy. It will cross with the lower lying virtual levels, or exhibit an avoided crossing in the case of equal symmetry, and may ultimately become the lowest virtual orbital. This implies that

---

the LF state corresponding to the excitation to "d_z^2" starts at high energy but is strongly dissociative and may eventually become the lowest excited state. Whether the LF state actually crosses the CT excited state and becomes the lowest excited state in the metal fragment resulting from CO dissociation of course depends on the magnitude of the CT excitation energy. We have found\(^2\) that if an equatorial CO dissociation in the \(\text{Mn(CO)}_5\) crosses the CT excited state and becomes the lowest excited state in the metal fragment, the remaining axial CO 5π* will become the lowest excited state upon lowering the symmetry from \(O_h\) to \(C_4v\). In these cases, the symmetry of the LF state resulting from excitation to "d_z^2" is equal to the symmetry of the lowest excited state at \(R_e\) (in the lower symmetry corresponding to the dissociating system). Since the LF state comes down, an avoided crossing between these states will occur along the dissociation coordinate. The first excited state PEC then either exhibits the typical barrier resulting from an avoided crossing, having the electronic structure of a LF excitation only after the barrier, or may be purely dissociative without a discernible barrier, the electronic structure in this case changing more gradually to the LF type. We have observed little tendency to formation of a barrier in the lowest excited state PECs for axial CO dissociation (none in triplet curves, very slight if at all in singlet curves). The state symmetry of the dissociative PECs is of course determined by the symmetries of the orbitals involved in the excitation, i.e. the highest occupied orbitals and the virtual dissociative "d_z^2" orbital.

The situation in \(\text{Cr(CO)}_6\) appears to be very much analogous to the axial CO dissociation in the Mn(CO)_5-L cases, the present \(1^1B_2\) and \(1^1E\) PECs that originate from CT states have the same characteristics as we encountered before: no \(1^1E\) or a small \(1^1B_2\) barrier in the singlet curves, none in the triplet curves. However, the presence of the remaining trans CO ligand, with high ligand field strength, gives some modifications compared to the investigated cases with weaker axial ligands L, which makes the picture of a simple (avoided) crossing between the dissociative LF state and the CT state slightly oversimplified. Let us consider the splitting of the relevant orbitals upon lowering the symmetry from \(O_h\) to \(C_4v\) (Scheme 1).

The \(\text{Cr-d}_{z^2}-\text{CO-5σ} \pi^*\) orbital has \(1^1A_1\) symmetry in \(C_4v\), the same as one of the components of the \(9t_{1u}\) orbitals. When an axial CO is moved away, this "d_z^2" orbital will come down. We would expect this \(a_1(6e_2)\) orbital to exhibit an avoided crossing with the \(a_1(9t_{1u})\). This means that the states arising from the \(2t_{2g} \rightarrow 9t_{1u}\) CT excitation, which have under the symmetry lowering become either \(e(2t_{2g}) ightarrow a_1(9t_{1u})\) or \(b_2(2t_{2g}) ightarrow a_1(9t_{1u})\), i.e. have \(E\) or \(B_2\) symmetry in \(C_4v\), will have an avoided crossing with \(E\) or \(B_2\) LF states that have the electronic character \(e(2t_{2g}) \rightarrow a_1(6e_2)\) or \(b_2(2t_{2g}) \rightarrow a_1(6e_2)\). These latter LF states are strongly dissociative. The avoided crossing may result in a barrier on the PEC, but if the crossing is strongly avoided no barrier will appear. It is actually found completely lacking in \(1^1E\) in Figure 2 and to be weak in \(1^1B_2\). Indeed, in the calculations the orbital energies of the \(a_1(6e_2)\) and the \(a_1(9t_{1u})\) orbitals never come very close—the \(a_1(6e_2)\) does come down in energy initially, but it does not get really close to the lowering \(a_1(9t_{1u})\) since at larger \(\text{Cr}-\text{CO}\) bond distances (2.0 Å and beyond) the \(a_1(9t_{1u})\) energy actually drops more quickly. So we do not have the simple picture that the \(a_1(6e_2)\), characterized by significant \(d_z^2\) character, on its way down crosses the \(a_1(9t_{1u})\), which has zero \(d_z^2\) character at \(R_e\) as well as at larger distances. The character of these orbitals changes in a somewhat more complicated way. Along the \(\text{Cr}-\text{CO}\) dissociation coordinate these two orbitals gradually but considerably mix, the symmetry lowering also giving rise to other orbital admixing, such as \(4p_z\). Ultimately the LUMO of \(\text{Cr(CO)}_5\), which evolves smoothly from the \(a_1(9t_{1u})\), has about as much \(d_z^2\) character as the higher lying \(a_1\) orbital, the latter however incorporating all of the antibonding with the axial CO that is left behind. We refer to ref 4 for a detailed discussion of these two \(a_1\) orbitals in Mn(CO)_5, which is very similar to Cr(CO)_5, with a full account of the role of the remaining axial CO 5σ orbital, the \(4p_z\) orbital, and the equatorial CO 2π* orbitals. We show in Figure 3 how the composition of the initially lower \(a_1\) orbital (starting as \(a_1(9t_{1u})\)) changes as a function of the \(\text{Cr}-\text{CO}\) distance. The building
of Cr-d\textsubscript{z}\textsuperscript{2} character in this orbital between 2.0 and 2.5 Å is clearly visible. In Cr(CO\textsubscript{5})\textsubscript{3} this orbital becomes the well-known d\textsubscript{z}\textsuperscript{2}-2π\textsubscript{eq} conj. LUMO with high amplitude at the vacant site and good acceptor properties. The change going from the a\textsubscript{1}(6e\textsubscript{g}) (i.e. "d\textsubscript{z}\textsuperscript{2}") to the a\textsubscript{1} LUMO of Cr(CO\textsubscript{5})\textsubscript{3} can be appreciated by comparing the contour plots of these orbitals in Figure 1, parts b and c. The plot of the Cr(CO\textsubscript{5})\textsubscript{3} LUMO shows the strong mixing of equatorial CO 2π with Cr 4p\textsubscript{π} and 3d\textsubscript{z}\textsuperscript{2} in this orbital. In view of the hybrid nature of the a\textsubscript{1} LUMO of Cr(CO\textsubscript{5})\textsubscript{3} one cannot unequivocally denote excitation to this orbital either as LF or as CT excitation. Nevertheless, the picture that the Cr–CO dissociation from a state that has CT character at R\textsubscript{c} can be understood from the (strongly avoided) crossing of this state by a strongly dissociative LF state captures the essence of the electronic structure explanation in the case of Cr(CO\textsubscript{5})\textsubscript{6} as well as in the Mn(CO\textsubscript{5})\textsubscript{L} cases.

It is clear now that among the states that arise from the 2t\textsubscript{2g} → 9t\textsubscript{1u} excitation those that can be derived from orbital excitation to the a\textsubscript{1} component (in C\textsubscript{4v} symmetry) of the 9t\textsubscript{1u} will be the ones that can give rise to states with dissociative PECs, either with a barrier or barrierless. The e(2t\textsubscript{2g}) → a\textsubscript{1}(9t\textsubscript{1u}) and b\textsubscript{2}(2t\textsubscript{2g}) → a\textsubscript{1}(9t\textsubscript{1u}) excitations give rise to E and B\textsubscript{2} states in C\textsubscript{4v}, respectively. All the other states from the (2t\textsubscript{2g})\textsuperscript{3}(9t\textsubscript{1u})\textsuperscript{1} configuration in O\textsubscript{h} corresponding to e → e excitation (A\textsubscript{1}, A\textsubscript{2}, B\textsubscript{1}, and B\textsubscript{2} states in C\textsubscript{4v}) and b\textsubscript{2} → e excitation (E state in C\textsubscript{4v}) are not expected to be dissociative. This is corroborated by the calculations of the PECs (see Figure 2). Most of the PECs (′A\textsubscript{2}, ′B\textsubscript{2}, ′B\textsubscript{1}, ′E) simply curve upward, the energy rising due to the loss of bonding to the leaving CO. It is interesting to observe that the ′A\textsubscript{1} state arising from the a\textsuperscript{′}T\textsubscript{1u} behaves somewhat differently. This is due to the changes in the electronic structure of this state along the dissociation coordinate. Upon Cr–CO bond lengthening this ′A\textsubscript{1} state originates from an e → e excitation. The virtual e orbitals that at R\textsubscript{c} belong to the antibonding CO-π\textsuperscript{*}–Cr-3d\textsubscript{z} 3t\textsubscript{2g} set, drop in energy due to loss of this antibonding character. The e orbital to which the excitation takes place goes down in energy and acquires considerable e(π\textsuperscript{*}–3d\textsubscript{z}) character. At longer bond lengths excitation to an orbital with much leaving CO π\textsuperscript{*} character implies an excited state with large charge separation (negative CO, positive Cr(CO\textsubscript{5})\textsubscript{3} fragment) and therefore corresponds to high energy. The ′A\textsubscript{1} PEC therefore goes up, but not very much since it experiences an avoided crossing with the first e → e ′A\textsubscript{1} excited state of the Cr(CO\textsubscript{5}) fragment. The asymptotic electronic character along this PEC is therefore this CT excitation in Cr(CO\textsubscript{5})\textsubscript{3}.

4. Conclusions

We conclude that the role of LF excited states in the photochemistry of TM complexes may be somewhat different than has been generally assumed. We find, in agreement with previous calculations on this and other d\textsuperscript{6} complexes with CO ligands (both DFT\textsuperscript{4–6} and CASSCF/CASPT\textsuperscript{2}), that LF excitations are at relatively high energy at R\textsubscript{c}. In the case of Cr(CO\textsubscript{5})\textsubscript{6} the low-energy shoulder in the spectrum has been attributed\textsuperscript{4} to a LF excited state, which appeared to be in agreement with the low intensity as well as its leading to photolytic metal–CO bond cleavage. We find in agreement with Pierloot et al.\textsuperscript{3} that symmetry forbidden transitions to low-energy CT states should be responsible for the absorption in the low-energy regime (ca. 4.0 eV). Some of these CT states are calculated to be dissociative, accounting for the experimentally observed photoactivity. The mechanism that makes the states dissociative is in essence (see above for details) the rapid lowering upon Cr–CO bond lengthening of Cr–CO antibonding LF states that are high lying at R\textsubscript{c}. The antibonding in the e\textsuperscript{*} orbital to which the excitation takes place in the LF excited states is strong, causing the high excitation energy, but it also appears to be rather short ranged, causing the orbital energy to drop rapidly upon bond lengthening. This lowering of the orbital energy has been apparent in previously investigated cases where the ligand field strength of the nondissociating trans ligand was relatively weak. In Cr(CO\textsubscript{5})\textsubscript{6} the remaining axial CO causes the dissociation to proceed without a clear (avoided) crossing of one-electron levels, but the rapid loss of antibonding between d\textsubscript{z}\textsuperscript{2} and the leaving CO causes considerable d\textsubscript{z}\textsuperscript{2} character to revert from the high-lying e\textsuperscript{*} to the lowest virtual orbital, while in the process the orbital energy of this orbital becomes lower, as does the energy of the states (E and B\textsubscript{2}) resulting from excitation from the HOMO 2t\textsubscript{2g} into this orbital. This makes the PECs of these states dissociative.

We have found the lowest Cr → 2π\textsuperscript{*} MLCT excited state, as well as various other types of lowest excited state that had very little or no metal–CO antibonding character, to be photoactive with respect to metal–CO dissociation. This demonstrates that it is not necessary to excite to LF states in order to induce photodissociation of ligands, and that such dissociation, when observed, does not prove that the excitation was to a LF state. However, the accepted picture that metal–ligand dissociation occurs from LF excited states is based on an underlying assumption, namely, that LF states are dissociative, which is fully corroborated by the calculations: they actually are so strongly dissociative that even if they are too high to be populated directly by irradiation into the lowest absorption band, they cross so soon with the lowest excited states that the lowest excited state PEC becomes dissociative.

Acknowledgement. We wish to thank Prof. D. J. Stufkens of the University of Amsterdam for exciting our interest in the photochemistry of metal–ligand bonds and for many suggestions and discussions. C.P. acknowledges support as an Erasmus exchange student in the project ICP-95-A-3008/13 (Prof. K. Schwarz, Vienna, coordinator).
