Manganese oxide catalyst

Catalytic activity

ABSTRACT

The statistical design-of-experiment method was used to identify the significant factors for making a manganese oxide-loaded activated carbon matrix. The carbon matrixes, which were made by reacting KMnO_4 with carbon material, were tested as gas-diffusion electrodes for oxygen reduction. Three factors— KMnO_4 concentration, reaction temperature, and reaction duration were tested in a two-level full-factorial design-of-experiment. The modification of carbon morphology and its effect on the performance of oxygen reduction are discussed. Temperature, KMnO_4 concentration, and the interaction between temperature and reaction time were found to have a significant influence on the catalytic activity of the manganese oxide-loaded carbon electrode.

1. Introduction

The search for clean and renewable power sources has been a major technological and environmental activity for several decades. Among the power sources being studied are primary and secondary battery systems, and a new generation of systems to be based on hydrogen fuel.

Air cathode has been widely used in energy conversion technologies, such as fuel cells and metal–air batteries. For example, zinc–air batteries have been used as hearing-aid batteries for more than 50 years and are currently sold for more than 500 million dollars a year worldwide [1]. Metal–air batteries and fuel cells have high energy density because the oxygen in the air is used as the active material in the cathode. Among the non-noble catalysts used in oxygen reduction reactions (ORRs), manganese oxide seems to be the most promising and widely used catalyst in an alkaline electrolyte because of its abundance, low cost, and high catalytic activity. Manganese oxides have also been extensively used as active material in the cathode in various battery systems, most notably primary alkaline MnO_2/Zn batteries.

ORR electrocatalyzed by manganese oxide was believed to occur through successive two-electron process with HO_2^- as intermediate. The reaction involves the reduction of O_2 to HO_2^- mediated by the Mn(IV)/Mn(III) couple, and MnO_x facilitates the HO_2^- intermediate species to disproportionate into O_2 and OH^- [2–6]. The catalytic activity of MnO_2 is closely related to its morphology and crystal structure, which rely on the catalyst synthesis and gas-diffusion electrode (GDE) making procedures. There are two different approaches to incorporate manganese oxide catalysts into the carbon support: mechanical mixing in which the manganese oxide catalysts are first prepared through various methods and then mixed with carbon support materials; or impregnation in which soluble Mn species in the solution are used as starting material, for example, soluble Mn(II) ions were first adsorbed into carbon support and manganese was oxidized to its high oxidation states through subsequent treatments. The advantage of the first approach is that the crystal structure of manganese oxide can be well-controlled; therefore many MnO_x -based alkaline air cathodes reported in the literature for ORR mechanistic studies were fabricated by mixing MnO_2 with high-surface area porous carbon materials [7]. However, the performance of these kinds of air cathodes largely relies on the homogeneity, uniformity, and conductivity of the matrix. Unfortunately, it is difficult to form a matrix of homogenous mixture between MnO_x and high-surface area carbon during bulk powder processing; the poor distribution of MnO_x in the carbon matrix results from the mechanical mixing of the two solid powders which have significantly different bulk densities.

Therefore, a high percentage of manganese catalyst may be needed to ensure high catalytic activity for ORRs [7,8].

The impregnation method is favored over mechanical mixing to achieve homogenous, highly dispersed catalyst distribution on the surface of high-surface area carbon electrodes, because uniform distribution of catalyst can be achieved more efficiently. Indeed, the impregnation method is preferred at the industrial production level, as seen in the method of MnO₂ preparation by reacting potassium permanganate (KMnO₄) with high-surface area active carbon material [9,10]. The permanganate is reduced by carbon mostly to MnO₂, and the forming MnO₂ catalyst is very uniformly distributed on the surface of carbon matrix. The important issues are the effects of KMnO₄/carbon reaction on the porous structure of carbon and its influence on the performance of the air cathode. The purpose of this work was to investigate such effects.

2. Experimental details

2.1. Materials

The high-surface area activated carbon material was purchased from Calgon, subsequently thermo-treated at 900 °C in a tube furnace under inert gas and reflux washed with acetone for 10 h. ACS grade (99.0% min) KMnO₄ was purchased from VWR.

Various kinds of MnO₂-loaded carbon materials were prepared by reacting KMnO₄ solution with carbon. 200 mL water was first poured into a 500-mL beaker, and 50 g of carbon was slowly added into the beaker with continuous stirring. After reaching the preset temperature, 80 mL of KMnO₄ of certain concentration was slowly added to the beaker and the reactor was kept at the preset temperature for different durations. The MnO₂-loaded carbon material was then recovered using a Buchner filter funnel. The solid was washed three times with deionized (DI) water and dried overnight in a 120 °C oven.

2.2. Electrolyte, reference and counter electrodes

Aqueous potassium hydroxide solution (30 wt.%) was used as the electrolyte in all experiments at 298 ± 2 K. All potentials reported were referred to the Hg/HgO reference electrode immersed in the KOH solution of the same concentration as the experimental electrolyte. A nickel mesh was used as counter electrode.

2.3. Construction of GDE and electrochemical cell

The GDE was made with 90 wt.% of catalyst-loaded carbon material and 10 wt.% of Teflon dry material. The Teflon suspension (T-30) used was from DuPont. The catalyst-loaded activated carbon was first wet with *iso*-propanol solution and then mixed thoroughly with T-30. The dough was subsequently hot-rolled into a thin film and then hot-pressed onto a Ni-mesh current collect using a hydraulic press.

Details of the construction of the electrochemical cell were reported previously [11]. The interfacial area between the GDE and the electrolyte was 95 mm².

2.4. Analysis of MnO₂ content in the loaded activated carbon

The MnO₂-loaded activated carbon material was first digested in 10% HNO₃ solution at boiling temperature. MnO₂ was then reduced to soluble Mn²⁺. The Mn²⁺ concentration in the solution was measured using inductively coupled plasma (ICP).

2.5. Experimental techniques and instrumental details

Electrochemical measurements were carried out using an EG&G 173 potentiostat-galvanostat controlled by a Q&R Smart Data Package. A Micromeritics ASAP 2020 porosimeter was used for measuring the surface area and porosity. Nitrogen was used as an absorbate gas. Density functional theory (DFT) software from Micromeritics was used for the calculation of pore distribution. Slit pore geometry was assumed. A Perkin-Elmer Optima 3000XL Inductively Coupled Plasma Spectrometer was used for the analysis of soluble Mn²⁺. The statistical software MINITAB was used for the design-of-experiment design and data analysis.

2.6. Design-of-experiment

Design-of-experiment helps to screen the multiple factors and determine which are important for explaining process variation and how factors interact and drive the process.

Factorial designs [12] enable the investigation involving multiple factors. Instead of the traditional experimental approach, or one-factor-at-a-time method, in which one parameter is changed while the other parameters are kept constant, several factors are allowed to vary simultaneously in factorial design. Unlike the single-factor experiment, factorial design-of-experiment can reveal not only the effects of individual factors but also their interactions, which can be studied. To perform a general factorial design, a fixed number of “levels” for each of a number of variables (factors) are chosen. Then, experiments with all possible combinations are run. The responses to the change of factors are analyzed using analyses of variance (ANOVA), which are used to uncover the interactive nature of reality, as manifested in higher order interactions. Although the factorial design is unable to cover entire ranges of all factors, it can indicate major trends. To determine the effect of each factor in a multiple variant environment, design-of-experiment is frequently used in the early stage of product development to determine a promising direction for further experimentation. It is also a good practice in fundamental scientific research to use a preliminary experimental effort to look at a large number of factors superficially rather than a small number thoroughly, so that the “big picture” is not missed. Although design-of-experiment does not reveal the underlying intrinsic scientific causes for the trends, it can pinpoint the significant factors, on which the mechanistic research should be focused [13].

The factors chosen to vary in this experiment were the most critical ones for the synthesis of MnO₂-loaded activated carbon material. A two-level full-factorial design (2³) was used for the study. All possible combinations of the levels of factors were tested with three replicates. KMnO₄ concentration, reaction temperature, and reaction duration were chosen as the factors to vary. The details of the two-level factorial design are listed in Tables 1 and 2. The samples were synthesized following the run order. The physical properties, such as surface area and pore distribution, and electrochemical performance of ORR were studied for each individual sample.

Table 1
Values of the three factors at two levels

Factors	Value of variable	
	Low level (–)	High level (+)
A: KMnO ₄ concentration (%)	2	10
B: reaction temperature (°C)	22	80
C: reaction duration (min)	10	40

Table 2

Test matrix and run order for the two-level full-factorial design

Run order	KMnO ₄ concentration (%)	Temperature (°C)	Time (min)
1	10	22	40
2	2	80	10
3	2	22	40
4	10	22	10
5	10	80	40
6	10	80	10
7	2	80	40
8	2	22	10

3. Results and discussion

3.1. Surface area and pore distribution of the MnO₂-loaded carbon material.

Given that electrocatalytic reaction is a surface phenomenon and only Mn on the surface would participate in the reaction, the accessible Mn species would be proportional to the catalytic activity. The MnO_x catalyst activity, therefore, is largely attributed to the surface area and surface defect of both MnO₂ and carbon. The surface area of a given mass of solid material is inversely related to the average pore width. The larger the surface area, the larger the percentage of small pores will be. The surface area of a solid could be contributed by external surface and internal pore surface. External surface includes the outer surface and all the pores that are wider than they are deep. The internal pore surface comprises the surface of pores which are deeper than they are wide. Obviously, from a mass transfer standpoint, the external surface and the surface of large pores are much easier to be accessed electrochemically than those of small pores. Therefore, it is very important to design the gas-diffusion electrode in such a way that the electrolyte can penetrate into but not over-flood it. A porous morphology and its interconnected pores have to provide sufficient

three-phase reaction zone and diffusion paths for both electrolytes and air.

Table 1 details the values of the three factors at two-level (2³) full-factorial design. The low and high levels of the factors were chosen wide enough to demonstrate statistical differences but within the range of practical feasibility. Table 2 tabulates the test matrix for the factorial design. Eight MnO₂-loaded activated carbon materials were prepared under the described conditions. The percentage of MnO₂, surface area, pore distribution, and electrochemical performance for ORR were measured for the eight samples and the blank carbon material.

Table 3 tabulates the percentage of MnO₂, average pore width, total surface area, and the surface area of the pore with widths less than 7 Å, 15 Å, and >15 Å. As the catalyst-loaded carbon contains MnO₂, the density of which is higher than that of carbon, the surface area of the composite and the surface area of the carbon in the composite are listed separately. The surface area of MnO₂ was assumed to be about 50–100 m² g⁻¹. It should be emphasized that the determination of the actual surface area of the MnO₂ formed in the pores of the carbon material is difficult, the assumption is based on the fact that the surface area of commercial electrolytic manganese oxide (EMD) is about 30–50 m² g⁻¹ [14], and the surface area of the MnO₂ synthesis from oxidation of Mn²⁺ by bubbling O₂ [15] and by KMnO₄ [16] was about 20 m² g⁻¹ and 80 m² g⁻¹, respectively. DFT was used to calculate the surface area and the pore width distribution. The traditional BET method was avoided, because it can significantly over-inflate the surface area for the microporous materials. DFT is based on a molecular-based statistical thermodynamic theory that allows relating the adsorption isotherm to the microscopic properties of the system: the fluid–fluid and fluid–solid interaction energy parameters, the pore width, pore geometry, and the temperature.

The outcomes of the statistical analysis for the experimental results are tabulated in Table 4. The impacts of the three chosen factors and their interactions on the percentage of MnO₂, matrix

Table 3Comparison of the percentage of MnO₂, surface area, surface area of carbon, surface area of pore <7 Å, <15 Å, and >15 Å, and average pore width

Sample	MnO ₂ (%)	Surface area (m ² g ⁻¹)	Surface area of carbon (m ² g ⁻¹) ^a	Surface of pore <7 Å	Surface of pore <15 Å	Surface of pore >15 Å	Average pore width (Å)
1	8.2	662	717–712	400	600	62	28.4

	α = 0.4	–	AC	AC	AC	AC	BC

‘–’ means no significant effect and ‘+’ means significant effect; ‘AC’ means the interaction between KMnO₄ concentration (factor A) and reaction duration (factor C).

^a Surface area.

surface area, carbon surface area, the surface area of pores $<7 \text{ \AA}$, 15 \AA , and $>15 \text{ \AA}$, and average pore width are evaluated at two alpha (α) levels. The α is the probability of rejecting the null hypothesis when the null hypothesis is really true, that is, finding a significant association when one does not really exist. It is also called the level of significance. For example, $\alpha = 0.1$ denotes finding an effect that does not really exist is 10%. In other words, if an effect is found to be significant, it would be 90% certain that it is true. It appears that the three factors and their interaction did not have significant effects to the responses at a 90% confidence level. However, it is 60% certain that KMnO_4 concentration would have significant effect on the surface area of the matrix; temperature would significantly influence the amount of MnO_2 -loaded on the surface; reaction duration would affect both the surface area and average pore width; the combination or interaction of KMnO_4 percentage and reaction time would have significant effect on the surface areas as well.

In a porous solid material, pores are formed within the particles of a fine powder, the primary particles, or in the aggregated secondary particles that are formed when primary particles stick together [17]. For high-surface area carbon materials, the primary particles can be considered as molecular space where the carbon atoms form a covalently bonded three-dimensional network; and within the network, imperfect layer arrangements can be recognized. The carbon microporosity is determined by the volume elements between the carbon atoms. Not all of the porosity of an activated carbon has the same entrance dimensions [18]. More porosity is open to molecules or ions of smaller width than to those with larger width. The availability of the pores to certain species is determined by the pore openings: the pore opening has to be large enough to allow penetration of the adsorbate. Closed porosity is defined as that porosity which is not accessible to a given adsorbate. There would be two kinds of closed pores: the ones that have an opening to the exterior of the grains and the sealed-off pores. Fig. 1A shows the comparison of the pore distribution of the activated carbon and two MnO_2 -loaded activated carbon materials. It appears that the reaction of KMnO_4 with carbon material would reduce the surface area of large pores (pores $>7 \text{ \AA}$) whereas it would increase the surface area of fine pores. The effects became more pronounced when the duration of the reaction was longer. The chemical reaction between permanganate and carbon reduces permanganate to MnO_2 and oxidizes carbon to CO_2 . The physical effects of the redox reaction on the carbon surface are two fold: first, the top layer of carbon will be removed by being oxidized to carbon dioxide; second, the MnO_2 fine particles that are formed will precipitate on the surface of carbon. The chemical reaction happens only if the permanganate could reach the carbon atoms; thus the initial redox reaction happens on the external surface of the activated carbon and within the large pores through which permanganate can penetrate. As the result of the initial reaction, solid MnO_2 would deposit on the walls of the large pores which will reduce the surface area of large pores. Meanwhile, surface carbon atoms would be removed and the removal of the top carbon layers would not only open up the sealed-off pores but also widen the opening of micropores. Thus the surface area of the initially closed pores, which had not been available to N_2 adsorbate, becomes accessible to the adsorbate gas.

It is worth noting that changes of porosity from sample to sample are small but significant. Additional experiments were done with various activated carbon materials in our labs, the trend that the surface of large pores was reduced and the surface area of small pore was increased after the KMnO_4 treatment has been consistently demonstrated. The results will be reported elsewhere. As shown in Table 4, it is above 60% certainty statistically that the response of pore surface area changes to the concentration of KMnO_4 , time and

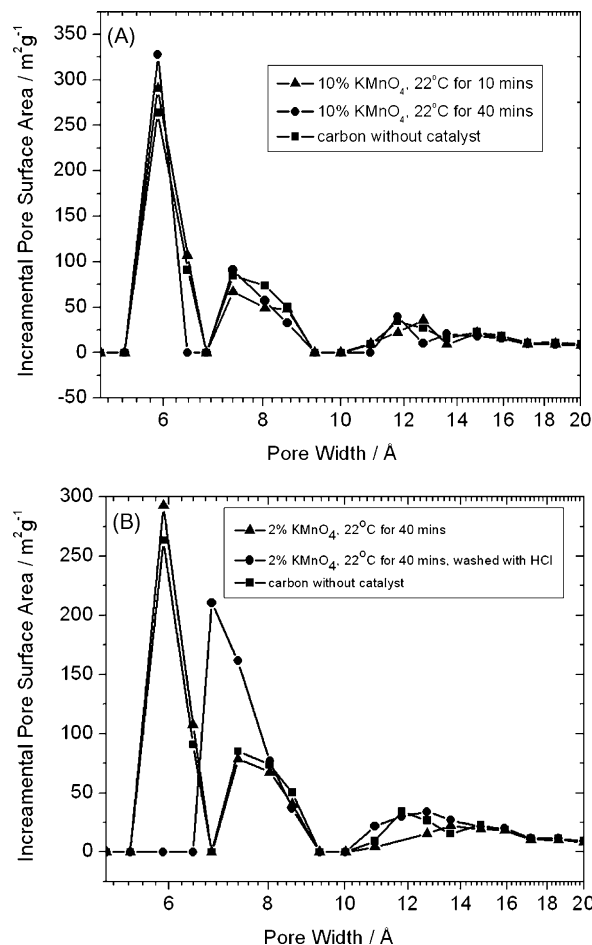

Fig. 1. Comparison of pore width distribution of blank activated carbon and manganese oxide-loaded carbon made by reacting 10% KMnO_4 solution with the activated carbon at 22 °C for 10 min and 40 min, respectively (A); comparison of pore width distribution of blank carbon, MnO_2 -loaded carbon and the carbon with MnO_2 removed by HCl washing (B).

the interaction between the two is significant. The surface modification of carbon by KMnO_4 can be further demonstrated in Fig. 1B, where the pore distributions of the blank carbon, MnO_2 -loaded carbon and the carbon with MnO_2 removed by HCl washing are

Table 5

Comparison of minimum overpotential and mA mV⁻¹ ratio for blank carbon and eight carbon matrixes made in the design-of-experiment

	Blank	1	2	3	4	5	6	7	8
Overpotential (mV)	-146	-96.1	-70	-116	-96.2	-78.5	-68.0	-58.9	-88.6
mA mV ⁻¹	0.417	0.104	0.395	0.267	0.201	0.299	0.216	0.461	0.367

compared. It is obvious that the pore width of small pores was significantly increased and more continuous pore width distribution was demonstrated.

3.2. Catalytic ORR on the surface of carbon composites

ORR is believed to undergo two successive two-electron processes with HO₂⁻ as intermediate. Manganese oxide was found to induce the disproportionation reaction of HO₂⁻ to O₂ and OH⁻ [3]. The GDE should have sufficient sites for the ORR. This relies on the structure of the carbon material, surface porosity and the distribution of catalyst. A material with more active sites would possess higher electrocatalytic activity. Fine-sized MnO₂ catalyst well distributed in the matrix of carbon would significantly increase the number of active sites by serving introducing catalyst. Fig. 2 shows the comparison of the potentiodynamic of ORR for blank activated carbon and two manganese oxide-loaded carbon electrodes. The slope of the reduction curve in the range of high overpotential (mA mV⁻¹), as shown in Fig. 2, can be used to estimate the catalytic activity of an activated carbon electrode. The determination of reduction overpotential is also shown in the figure.

Table 5 tabulates the starting potential and mA mV⁻¹ values of ORR for blank activated carbon and eight catalyst-loaded carbon electrodes. The starting potential represents the minimum overpotential for the oxygen reduction. Table 6 lists the results of the statistical analysis on the influence of the factors and their interaction on minimum overpotential and mA mV⁻¹ ratio. It clearly demonstrates that the mA mV⁻¹ ratio, the catalytic activity, was determined by both permanganate concentration and reaction temperature with 90% certainty. The reaction temperature had a significant effect on the minimum overpotential at the same confidence level. Even though reaction duration may not have a significant influence on both minimum overpotential and mA mV⁻¹ ratio at the high certainty level, the interaction between temperature and reaction time definitely has a significant effect on mA mV⁻¹ ratio. Fig. 3 shows the main effects plot for the factors with 90% confidence influence. Only the factors with high confidence as shown in Table 6 are used in Fig. 3. As shown in Fig. 3A, the catalytic activity for the ORR increases with the increase in reaction temperature and the decrease in permanganate concentration. The ORR minimum overpotential decreases as the reaction temperature increases as shown in Fig. 3B. The effect of reaction time on the catalytic activity, however, relates to the reaction temper-

ature. At low temperature (22 °C), the catalytic activity increases with reaction time, whereas the reverse trend is demonstrated at high reaction temperature (80 °C). In summary, systematic statistical studies indicate that high-performance MnO₂/carbon matrix should be synthesized using a low concentration of KMnO₄, at high temperature for relatively longer reaction duration. Indeed, sample no. 7, which was made by reacting 2% KMnO₄ solution with the carbon material at 80 °C for 40 min (Table 2), demonstrated the best performance with low minimum overpotential and high catalytic activity (Table 5).

Catalytic oxygen reduction in the GDE is a surface phenomenon in which the catalytic process involves the interactions among oxygen, electrolytes, manganese oxide catalyst, and carbon support material. The number and active sites would be an important factor for the reduction kinetics. Evidentially, the carbon/catalyst matrixes made at high temperature have less minimum overpotential than those made at low temperature. The catalytic activity of manganese oxide depends strongly on the Mn oxidation state, as well as on the oxide structure. Different catalytic activities were reported for ORR on manganese oxides of different crystal structure [2,4]. It appears that the reaction temperature plays a dominant role in determining the ORR overpotential catalyzed by manganese oxides. This may be a result of the various structures exhibited by manganese oxide and the minor differences in Mn oxidation states. Owing to the low percentage of highly defect MnO₂, any possible MnO₂ diffraction peaks would be covered by the board [002] and [100] carbon diffraction peaks, an example of XRD patterns

is included in online supplementary information. The hypothesis is under investigation using in situ X-ray absorption spectroscopy, which could reveal the information of short-range coordination and the change of Mn oxidation state. The results will be reported later.

The GDE structure should not only have high electronic conductivity to ensure low Ohmic resistance, but also provide a high three-phase interfacial area and a short diffusion path for quick mass transfer. The cathode with highly opened microporous structure would provide the pathway for the fast gas and electrolyte diffusion. Fig. 4 shows the comparisons of electrochemical performance and pore distribution of the blank activated carbon and the two MnO₂-loaded carbon matrixes. It seems that the minimum overpotential of catalyzed electrodes was less than that of a blank carbon electrode (also refer to Table 5). The mA mV⁻¹ ratio, however, was also related to the pore distribution. The electrode with the larger percentage of big pores would have a larger mA mV⁻¹ ratio than those with a small percentage of big pores. The carbon matrix with a highly open microporous structure, which could facilitate rapid mass transfer, is essential for a high-performance GDE. The ORR kinetics are related to the local current density. The larger the effective area, the lower the local current density and the faster the reaction kinetics would be. During ORR, oxygen molecules and OH⁻ diffuse through the network of interconnected pores and the residence times would be longer in the smaller volume elements of the porosity because of the curvature effect. This effect is more pronounced for gas-diffusion than ion diffusion. The effect occurs in pores that are narrow enough for the whole of the adsorbate to be in range of the forces originating from the solid surface. At this

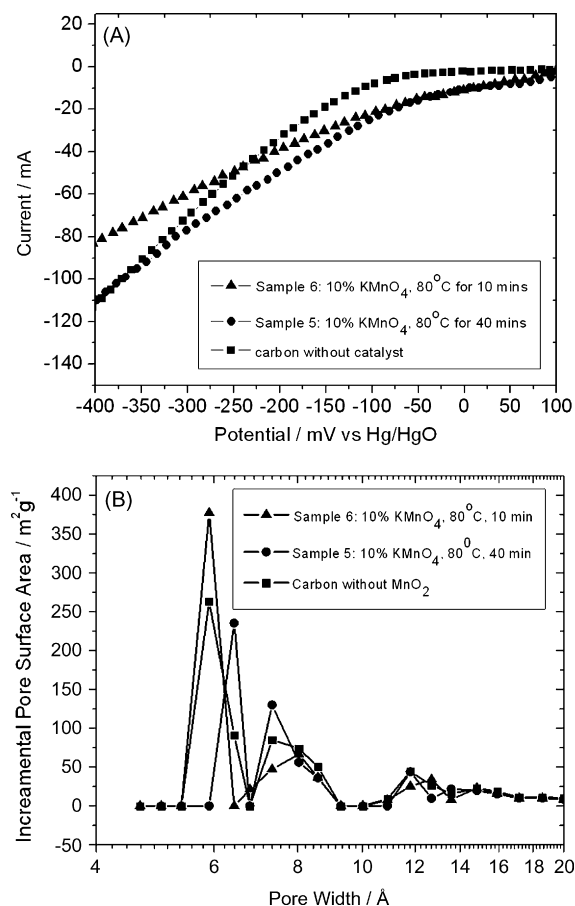

Fig. 5. Comparison of potentiodynamic for ORR on the gas-diffusion electrode made by blank carbon, carbon matrix synthesized by reacting 10% KMnO₄ with the carbon at 80 °C for 10 min and 40 min (A) and their pore distribution.

distance, the influence of the surface of neighboring walls would overlap, so the interaction energy of the solid with a gas molecule would be correspondingly enhanced. Such curvature effects only occur in pores with a width not exceeding a few molecular diameters [19]. The diameter of oxygen is 3.55 Å [20]. It was suggested that a pore diameter in the order of 18 Å would be required to facilitate an effective ORR and only the large pore surface should be considered as an effective reaction interface [11,21]. Therefore, even though the oxidation of a carbon surface by permanganate could make some closed pores available to N₂ adsorbate during the measurement of isotherms, those pores may not be available to ORR. However, if the surface of large pores was reduced by MnO₂ precipitation; the effective surface area for ORR would be reduced after the catalyst was loaded. This phenomenon is demonstrated in Fig. 4. Finally, Fig. 5 shows the ORR potentiodynamic profiles and the pore distribution on the manganese oxide-loaded carbon made with higher KMnO₄ concentration at higher temperature than those in Fig. 4. The same trend was demonstrated in Fig. 5 as that of Fig. 4. However, even though MnO₂-loaded carbon electrodes in Fig. 5 demonstrated high catalytic activity, the advantage gradually disappeared as the current increased. As shown in Table 3, the percentage of MnO₂ in samples 5 and 6 (electrodes in Fig. 5) was much higher than that in samples 3 and 8 (electrodes in Fig. 4). MnO₂ is a typical semi-conductor. In addition to the polarization resulting from both sluggish charge transfer and mass diffusion limitations would also add to that arising from a lack of catalytic sites for oxygen reduction and rate limited the oxygen supply. Ohmic IR polarization starts to play an important role as the current increases.

4. Conclusions

Systematic design-of-experiment investigation reveals the significant effects of the main factors and their interactions on the physical characteristics of manganese oxide-loaded carbon matrix and on their catalytic activities for ORR. Permanganate was believed to react with carbon material forming manganese oxide deposits and carbon dioxide. As the results of the redox reaction, some of the closed micropores were opened for the access of N₂ adsorbate during the porosity measurement because of the removal of the surface carbon layers. The surface of pores with width less than 15 Å may not be available for ORR. Manganese oxide was deposited on the external surface and the surface of large pores; the large pore surface area was reduced, which had a negative effect on ORR. A significant factor that influenced the minimum overpotential was the reaction temperature: the higher the temperature, the less the overpotential would be. It was proposed that the crystal structure of manganese oxide and the oxidation state of Mn could

be different for the materials made at different temperatures. The ratio of mA mV⁻¹ was significantly influenced by KMnO₄ concentration, reaction temperature, and the combination of temperature and reaction duration.
